

# Systems for Big data

Authors :

- Randy ZEBAZE DONGMO
- Paul FOTSO KAPTUE

# Presentation of the problem

Purpose :

- ❖ Familiarize with use of MapReduce
- ❖ Solve big data problems with the use of Hadoop and Spark

# Integer Manipulation with Apache Spark

- ❖ We want to compute the largest integer in the file
- ❖ We use a first map to cast the lines of our RDD to integers
- ❖ After that we use a reduce operation to compute in parallel the different maxima and aggregate them.

# Average of all the integers

- ❖ We want to compute the average of all the integers
- ❖ Firstly we compute the sum by using a MapReduce operation:
  - Map for cast the lines of our RDD to integer
  - Reduce to compute the sum
  - We use the count function in order to find the number of elements

# Output all the distinct integers

- ❖ We want all the distinct integers
- ❖ We use a Map operation to map  $x$  to the tuple  $(x,1)$
- ❖ We ReduceByKey and we obtain all the distinct integers and their occurrence
- ❖ We finally save the keys

# Number of distinct integers

- ❖ We want the numbers of distinct integers
- ❖ We use the previous pairRDD (distinct integer, number of occurrence) and we apply the `count()` function on the RDD which contains its keys.

# Integer Manipulation with Spark Streaming

# Largest of all integers

- ❖ We want the largest integer
- ❖ We begin by storing our file in a Dstream
- ❖ We apply the MapReduce to this Dstream as we did when using RDD
- ❖ We use list that contain the largest integer per batch of the stream
- ❖ we use the foreach function of RDD to update the list and print the current maximum who is equal to  $\max(\text{old-max}, \text{actual-batch-max})$

# Average of all the integers

- ❖ We want the average of all the integers
- ❖ We start by storing our file as a Dstream
- ❖ We apply a Map  $x \rightarrow (x, 1)$  followed by a Reduce  $((x1, y1), (x2, y2)) \rightarrow (x1 + x2, y1 + y2)$
- ❖ We use 2 lists, one containing the sum of integers per batch, and the other containing the number of integers per batch
- ❖ We use foreachRDD to update these 2 lists and the value of the average we output

# Number of distinct integers

- ❖ We want the number of distinct integers
- ❖ We are going to use the Flajolet-Martin Algorithm, so we choose a **hash function**  $h$
- ❖ We start by storing our file as a Dstream
- ❖ We apply a Map  $x \rightarrow$  ***trailing zeros*** ( $h(x)$ )
- ❖ We use a list that store the maximum number of trailing zeros per batch
- ❖ We use foreachRDD to update the list and output  $2^{\wedge}$  (The current maximum number of trailing zeros)

# Ranking wikipedia web pages

- ❖ We have a graph  $G$  where :
  - Nodes : wikipedia web pages
  - Edges : hyperlinks between pages
  - PySpark API

# Eigenvector centrality computation

With Apache Spark:

- ❖ Two steps matrix multiplication
- ❖ Computation of the norm with one MapReduce

# Most important pages in Wikipedia

- ❖ Build an RDD that map each pages to it index
- ❖ Compute  $rt$  by our matrix multiplication algorithm
- ❖ This algorithm return  $rt$  as a `pairRDD<Integer,Double>(index->importance)`
- ❖ We used the `max()` method to get the index with the maximum importance value
- ❖ Finally we apply the `lookup()` method to find the corresponding name

# Matrix Multiplication

We define a matrix element by three attributes:

- ❖ Row number
- ❖ Column number
- ❖ Corresponding Value

Matrix Format storage :

- ❖ We store the matrix A in RDD where line are in the form  $(i,j,a_{ij})$
- ❖ We store the matrix B in RDD where line are in the form  $(j,k,b_{jk})$
- ❖ We don't store null elements

## Using Two MapReduce steps

- ❖ We used a first Map to send each matrix element  $a_{ij}$  respectively  $b_{jk}$  to the pair  $(j, (A, i, a_{ij}))$  respectively  $(j, (B, k, b_{jk}))$
- ❖ For each  $j$ , we examined its lists of values, and for each value that comes from  $A$   $(A, i, a_{ij})$  and each value that comes from  $B$   $(B, k, b_{jk})$  we produced the tuple  $(i, k, val = a_{ij} * b_{jk})$
- ❖ We used a reduce to output  $(j, [(i_1, k_1, val_1), \dots, (i_q, k_q, val_q)])$
- ❖ We flattened the previous pairs to produce  $q$  pairs  $((i_1, k_1, val_1), \dots, (i_q, k_q, val_q))$
- ❖ For each key  $(i, k)$  we used a reduce operation to sum all its associated values
- ❖ We ended up with a pair  $((i, k), v)$

# Using one MapReduce Step

- ❖ We use a Map to, for each  $a_{ij}$  of  $A$  produce pair  $((i,k),(A,j,a_{ij}))$  for  $k = 1 \dots$  up to the number of columns of  $B$ .
- ❖ The same operation for each  $b_{jk}$  of  $B$  to produce pair  $((i,k),(B,j,b_{jk}))$  for  $i = 1 \dots$  up to the number of columns of  $A$
- ❖ For each  $(i,k)$  we have a list of value  $(A,j,a_{ij})$  and  $(B,j,b_{jk})$  for all possible  $j$
- ❖ We associated the two values that have the same  $j$ , for each  $j$  by:
  - Sort by  $j$  the values that begin with  $A$ , and do the same for values that begin with  $B$  in separate lists
  - We extracted and multiplied the third components  $a_{ij}$  and  $b_{jk}$  of the  $j$ th values of each list
  - theses products are summed up and paired with  $(i,k)$

## Cost of computing eigenvector centrality

$\text{cost} = \text{\#iterations} \times (\text{cost}(\text{matrix multiplication}) + \text{cost}(\text{vector normalization}))$

## Cost with two mapreduce steps

- ❖ The first map produces  $m$  tuples coming from  $A$  because we store only non-zero's elements and (at most)  $n$  tuples coming from  $B$ . We end up with  $m+n$  tuples
- ❖ The second Map produce for each  $j$  at most  $\text{degree}(i)$  tuples and for all  $j$  we have  $m(\text{sum of all degree}(j))$  tuples which are send to the reduce
- ❖ With the formula above, we have:
- ❖  $\text{Cost} = k * ((2m+n) + O(n))$

## Cost with one MapReduce step

- ❖ The Map produces  $m$  tuples coming from  $A$  and  $n^2$  tuples coming from  $B$
- ❖ We ended up with  $m+n^2$  tuples to send to the reduce
- ❖ With the cost generic formula above we have:
- ❖  $\text{cost} = k * ((m + n^2) + O(n))$
